Abstract: Precipitation is one of the most important factors determining the occurrence of extreme hydro-meteorological events and water resource availability. Precipitation in different grades has diverse ecological effects, and slight precipitation (SP, defined as 0.1 - 1.0 mm/day) is the minimal level among them. In this study, we investigated SP trends from 1961 to 2013, as well as the relationship between SP and advanced very high radiometric resolution (AVHRR) normalized difference vegetation index (NDVI) in China during growing season from 1981 to 2006. The distributions and trends of SP were analysed by calculating the daily precipitation data. The average annual slight precipitation amount (SPA) and the number of slight precipitation days (SPD), derived from 839 monitoring stations in China, show a decreasing trend over the last five decades, which is in agreement with total precipitation (TP) but in different rates. When the trend was analysed seasonally, SP in most stations decreases significantly in September-October-November (SON) and June-July-August (JJA), and the largest decrease is found in SON. About 49.5 and 68.7% of monitoring stations show a decreasing trend in SON, in both SPA and SPD, whereas the trend is less popular in March-April-May

(MAM, SPA: 19.7%, SPD: 41.4%) and December-January-February (JFJ, SPA: 25.6%, SPD: 43.1%). Moreover, our analysis indicates that the decrease of SP is mainly due to the decrease of SPD as the median amount of daily SP was unchanged over the past five decades (close to 0.3 mm/day). Based on 26-year (1981-2006) semi-monthly AVHRR NDVI data and the records of SP data, the relationship between AVHRR NDVI and SP was also investigated. In regions with lower (<600 mm) TP, the correlation coefficients between NDVI and SP tend to be higher. These results highlight that SP has different effects than TP on vegetation growth. We also analysed time lag effects and concluded that the sensitivity of NDVI to SP for grass vegetation (the correlation coefficient is 0.327) is more noticeable than for trees (0.211) or shrubs (-0.058). The relationship between SP and NDVI also provides us new insights on the dependence of vegetation growth on meteorological factors.

Key words: slight precipitation, multiyear trends, NDVI, growing season, space correlation.

1. Introduction

Climate change has not only beneficial impacts on the natural ecosystem but can also have detrimental influences on the natural ecosystem and human society (IPCC, 2013), and precipitation is among the vital aspects of climate change research. Temperature and precipitation are among the most relevant meteorological variables for hydrological impact studies (Xu, 1999; Bronstert et al., 2007). The latter is also the most important driver for both agricultural production and freshwater resources (Kundzewicz et al., 2007). Thus, as a key physical process, precipitation connects climate, weather and water cycle together (IPCC, 2007). It is noteworthy that precipitation has also changed remarkably over the past few decades in steps with climate change, which was mainly reflected in the increase of total precipitation (TP) in mid- and high latitudes over continental regions (Jones et al., 2007; Trenberth, 2011). China stretches across vast area, covering diverse climate regimes (including low, middle and high latitude) and is subject to the effects of precipitation variation, including floods and droughts (Zhang et al., 2006; Qin et al., 2007; Wang and Zhai, 2008). Therefore, variation and distributions of precipitation in China have received prevalent concerns (Qin and Qian, 2006; Wang et al., 2006; 2011; Min and Qian, 2008; Xu et al., 2014). Further studies showed that, although annual precipitation in China has remained stable over recent decades (Liu et al., 2005), it varied seasonally and regionally (Wang and Zhou, 2005; Zhai et al., 2005; Ma and Fu, 2006). For example, there is more precipitation in winter and summer, but less in spring and autumn, and the amounts of precipitation showed a “+, -, +” pattern from northeast to southwest; it increased in northwest China (NWC) and decreased in north China (NC) (Wang et al., 2006).

According to the China meteorological industry standard norms (Fu et al., 2008; Li et al., 2013), daily precipitation rates at monitoring stations are classified into six grades of intensity. They are trace (no amount), slight (≤ 1 mm/day), small (> 1 mm/day, < 10 mm/day), large (≥ 1 mm/day, < 50 mm/day), heavy (≥ 50 mm/day, < 100 mm/day) and very heavy (≥ 100 mm/day). Extensive studies mainly pay attention to changes in the last four grades (Fu et al., 2008; Li et al., 2013; Zhang and Wu, 2014), and extreme precipitation events have been the focus of studies (Alexander et al., 2006; Steensen et al., 2011; Shastri et al., 2015). Nevertheless, precipitation in small scale, especially slight precipitation (SP), has not been studied as much before. Hence, the trends of SP as a function of time are poorly understood. In contrast to extreme precipitation, SP is beneficial to plant growth. Extreme precipitation happens generally over a short time span, causing floods and runoff, whereas SP is able to penetrate into the soil, which has a strong effect on soil moisture (Trenberth et al., 2003; Trenberth, 2011). Previous researchers also pointed out that the frequency of days with precipitation is as important as precipitation amount and is more susceptible to climate change (Karl and Knight, 1998; Trenberth et al., 2003). Because of the shortage of studies on SP, there is a considerable research gap in the field of the frequency of days with SP. Here, we address this gap by focusing on both slight precipitation amounts (SPA) and slight precipitation days (SPD) in China. Only a few researchers have investigated the spatio-temporal variation of SP over China (Yan and Yang, 2000; Fu et al., 2008; Gao and Wu, 2014). Some studies found that SP in China shows a consistent decreasing trend, which is reflected in the reduction of drizzle days, particularly over the northern region of China (Yan and Yang, 2000; Qian et al., 2007b; Fu et al., 2008). Nevertheless, these studies did not detail the regional and seasonal SP trend over Mainland China, and this is what this study demonstrates. We analysed a greater number of measuring stations compared to what previous authors have considered. In addition, SP plays an important role in the growth of natural vegetation (Qian et al., 2007a; Zhang and Wu, 2014), while there is no analysis, to our knowledge, of the relationship between SP and the growth condition of vegetation greenness (NDVI) at a national scale. The growing state of the vegetation is linked to climate factors (Jackson et al., 2001; Bonan, 2015) – mainly through temperature and precipitation variations (Prasad et al., 2005). Gomez-Mendoza et al. (2008) pointed out that those changes in precipitation with various time scales have effects on the spatio-temporal variation of NDVI of different vegetation types. Precipitation has proved to be the most important climatic factor that correlates with NDVI, especially in semi-arid areas (Al-Bakri and Suleiman, 2004). Yet, the quantitative relationships between SP and NDVI have not been studied over wide regions of the world.

The purpose of this work is twofold. First is the identification of regional SP trends in China. We characterized the spatio-temporal variation of SP, interannual and seasonal trends of SPA and SPD in eight regions over China using intensive ground meteorological station data from 1961 to 2013; the determination of which one (SPA or SPD) makes the

most important contribution to changes in SP was also discussed. Second was analysing the relationship between SP and natural plants. The correlation coefficients between SP and NDVI during growing season (May to September) for various types and regions in corresponding period (from 1981 to 2006) were documented, and time lag effects were also taken into consideration.

Materials and methods

2.1 Datasets

Climate Data

Daily data from 839 stations were obtained from the Chinese National Meteorological Center (http://data.cma.cn/data/cdcdetail/dataCode/SURF_CLI_CHN_MUL_DAY_V3.0.html), which includes daily maximum surface air temperature, daily minimum surface air temperature and daily TP (including total precipitation amount [TPA] and total precipitation days [TPD]), and the digital display is accurate to one decimal place. Detailed information is listed in Table S1. The number of observational stations in service has changed in number over time as well. In the early 1950s, the number of stations increased from 160 to 400. Since 1958, the number that measure precipitation and temperature has remained at around 660. No measurement protocol changed during our study period. We used this data series of daily precipitation from 1961 to 2013. To avoid biases caused by missing values, we discarded stations where daily precipitation was recorded with missing values of more than 3 months within a single year or more than 12 months over the whole observational period, following Xu et al. (2014). We also applied methods to deal with the problem caused by changing the position of the stations, as Hawkins (1977) did. After considering the homogeneity of station distribution as well, we used daily precipitation data for the analysis, derived from 735 stations in total from 1961 to 2013 (See distribution pattern in Figure 1). For the missing data remaining in these stations, the averages of the nearest four stations were used in place of the absent value in the observational data before the subsequent analysis.

AVHRR NDVI Data

The biweekly NDVI data of 1981–2006 used in this study were obtained from the Pathfinder Data Sets of the EOS (Earth Observation System) data centre in the United States and the GIMMS 2g dataset of NOAA-AVHRR NDVI 15-day synthesized data (<http://ecocast.arc.nasa.gov/data/pub/gimms/>) from July 1981 to September 2006 (a total of 26 years). The maximum value of the two fortnightly data points was considered a monthly value, and the data resolution is 8 km.

We captured the dataset covering Mainland China.

Vegetation Data

We also analysed the relationship between SP and NDVI of natural vegetation from different types, including coniferous forest, broad-leaved forest, shrub, desert, grassland, grass cluster, meadow and marsh, derived from The Vegetation Map of China IOB (2007). This map was edited by the Institute of Botany, Chinese Academy of Sciences, and was published by China Atlas Press (Figure S1) (<http://www.nsii.org.cn/mapvege>), depicting the vegetation distribution over the area of this study. We reclassified these several types of natural vegetation into five basic types according to their shapes and habits (Changyong, 2011), namely, trees, shrub, desert, herbage and marsh, for further correlation analysis.

2.2 Methods

We showed the general pattern of SP over the past 50 years via two maps (both SPA and SPD). In order to explore the spatio-temporal variations of SP, first, China was divided into eight regions to analyse the spatial distribution of SP, namely, northeast, NC, central China (CC), northwest, southwest1, southwest2, south China and east China (EC) (Figure 1) following previous studies (Cheng, 1991; DFCH, 2006; IOB, 2007). These eight areas were divided by latitude and longitude, mainly according to ecological factors and geographic conditions (Gu et al., 2017). Second, 3-year moving averages and the accumulative anomaly method were used to analyse the trend of SP as a function of time. Moving average value is calculated from a time series of n to the average of multiple m consecutive sequence; for detailed information and operation, refer to Booth et al. (2006) and Chiarella et al. (2006). Both of these methods are useful for demonstrating long-term trends and are good at presenting turning points.

Seasonal trend

Daily SP was aggregated to seasonal sums of each region, including March to May (MAM), June to August (JJA), September to November (SON) and December to February (DJF). Table 1 shows the statistics of annual SP in China (CN) and in eight regions over the last five decades. A positive kurtosis in China indicates that the concentration of both SPA and SPD around the average is lower than that of normal distribution. Similarly, SPA and SPD in eight regions are not identical to the normal distribution. Therefore, to derive the change of SP in different seasons, we estimated the trends of the SPA and SPD by using a Mann-Kendall trend analysis method for all sites (see detailed method in SI) and the statistical significance of the slope, or its p-value, given by the Student's t test.

Regional climate tendency

In order to analyse the interannual climate tendency, we estimated the trend of SP in the eight regions using least square linear regression of SP (SPA and SPD) against the year. The linear regression ignores the interannual and interdecadal change of small scale while analysing the trends of precipitation; therefore, this method helps us derive the trend of SP in the long term (Ning and Qian, 2008). We derived the SP trend rate by calculating the slope of the least square linear regression; a positive value of the result indicates an “upward trend,” and a negative value of the result indicates a “downward trend” (Xu et al., 2014).

Median method

The median is a popular summary statistic used in descriptive statistics, and it is not skewed so much by extremely large or small values compared to the mean (Rousseeuw and Bassett, 1990). Therefore, we also selected a median amount of daily SP as an indicator to demonstrate whether SPA or SPD contributes more to the variation of SP.

Space correlation

Because the state of crops is affected by human practices, such as irrigation, we restricted the analysis of the relationship between SP and NDVI to natural vegetation. We extracted the spatial distribution ranges of each type of natural vegetation using Geographic Information System (GIS) technology and then overlaid them with the location of each meteorological station. Subsequently, all the monitoring stations corresponding to each category region were marked. Following Li et al. (2002), the NDVI value from the data of AVHRR NDVI was extracted according to the location of the monitoring stations. Then, we calculated monthly maximum NDVI of two biweekly periods in the same month (Li et al., 2002) and monthly SPA and SPD during the growing season, from May to September. Finally, we calculated the correlation coefficients between SP and NDVI for each region of China and vegetation type using Statistical Product and Service Solutions (SPSS) (Spearman as this method is robust to outliers). The correlation coefficients were computed by retaining both the trends in NDVI and in SP series.

3. Results and Discussions

3.1 The spatio-temporal variation of slight precipitation

The spatial distributions of SPA and SPD over 1961–2013 are shown in Figure 2. The maximum SPA values (>30.0 mm)

appear in southwest China (e.g., Sichuan, Guizhou and Chongqing), consistent with Wu (2012). Wu (2012) revealed that light precipitation appears over southwest China primarily. In addition, SPA mainly distributes in the northeastern forest zone and northwest Xinjiang. Minimum SPA values (< 6.0 mm) are found in NWC (e.g., Inner Mongolia and south-central Xinjiang). The SPD distribution shows a similar spatial distribution than SPA (Figure 2b). The SP distribution differs from that of TP in China – the latter one exhibits a gradual decrease from southeast to northwest (Figure S2). This difference is partly explained by the fact that the origin of SP is closely linked with the formation of rain, including convective, local frontal and orographic, while it is more sensitive to environmental factors, such as the variable aerosol particle concentration (Qian et al., 2009), and to orography compared to more intense precipitation in other grades.

The spatial distributions of SPA and SPD over 1961-2013 are shown in Figure 2. Maximum SPA values (> 30.0 mm) appear in Southwest China (e.g. Sichuan, Guizhou and Chongqing), consistent with Wu (2012). SPA also shows large values in the extreme north of Northeast China and Northwest China, corresponding to mountainous areas in mid-latitudes. Minimum SPA values (< 6.0 mm) are found in most areas of NWC (e.g. Inner Mongolia and south central Xinjiang). In a general manner, SPD shows a similar spatial distribution (Figure 2b). It is worth to note that the SP distribution differs significantly from that of total precipitation (TP) in China, the latter exhibiting a gradual decrease from southeast to northwest (Figure S2). This difference is certainly a revelatory element of the fact that SP has its own formation mechanisms and conditions that are distinct from intense precipitations. SP is thought to be more sensitive to environmental factors, such as abundance of aerosol particles (Qian et al., 2009) and to orography.

3.1.1 Long-term trend of SP

Trends of annual SP (SPA and SPD) and 3-year moving averages in the past 50 years are shown in Figure 3. The main information that can be derived from this figure includes the following: the highest SPA 3-year values (18.6 mm) for this moving average analysis occurred from 1964 to 1966, and the lowest one (14.8 mm) occurred from 2007 to 2009. The annual mean SPA indicated an exceptional peak in 1964, reaching 20.0 mm. Low ebb occurred in 2007. Significant decline trends in both SPA (Figure 3, panel a) and SPD (Figure 3, panel b) were observed on these figures. This result confirms the finding in Qian et al. (2009), suggesting that SP underwent a decreasing trend in eastern China over the past 50 years. It is also consistent with Huang and Wen (2013), who analysed drizzles for lands around the globe and found a decreasing trend for China and most of the Eurasian continent. They concluded that the atmospheric stratification stability related to global warming is the possible contributor to the decreasing trend in China from 1961 to 2010,

although the precise cause for the trend of SP in China is still unclear. Some authors also pointed out the important role played by aerosols that may affect precipitations through multiple processes, such as direct radiative effects, nucleation and heating effects of carbonaceous aerosols (Koren et al., 2005; Rosenfeld et al., 2008). Gao and Wu (2014), in a further study, showed that the SP decline in eastern China is largely caused by increases in aerosol loads: regions with higher aerosol optical depth (AOD) (high aerosol load) tend to have more severe decreasing trend in SP.

To describe the spatio-temporal behaviours of SP well, we used the Mann-Kendall Test for each of the 735 monitoring stations over the past 50 years (Figure 4). Results clearly confirm the negative trend identified for the whole of China over the past five decades (SPA: -0.0637 mm/year, $p < .05$; SPD: -0.3261 days/year, $p < .05$). In addition, we analyse the spatial distribution of SPA trends for each station (see Figure 4a). SPA shows significant negative trends in the southeast half of China, including the Bohai Bay coast, the NC plain, the middle and lower reaches of the Yangzi River and the southeast hills and most of southwest China (the number of monitoring stations with a positive trend is being very scarce over these regions). Most of the regions where SPA shows positive trends (although not significant) are located in the northwest half of China, including the mountainous areas in northern Xinjiang, Hetao plain and a few areas in the southern part of the Tibetan Plateau. The spatial structure of SPD trend is highly consistent with SPA in China over the last five decades (as shown in Figure 4b). Overall, more than 40% of the 735 monitoring stations show a decreasing trend in both SPA (40.0%) and SPD (66.0%). In conclusion, if we plot an imaginary line from the northeast to southwest (Heihe-Tengchong line; see the red line in Figure 1, which is an important line in China for both physical and human geography [Yue et al., 2003; Chen and Chen, 2008]), we will separate China into two parts. The majority of measuring stations southeast of this line shows a significant negative trend but a positive trend (although not significant) northwest of this line, both in SPA and SPD. Cities located in the southeast of this line are densely populated and well developed, with substantial industrial pollutants and aerosols emissions. However, it is the opposite condition in the northwest regions of Heihe-Tengchong Line. The better ecological environment and special orography might be the reason for fewer aerosols in northwest regions, which would cause an increasing trend of SP at several monitoring stations (Berg, 1971). This result is consistent with the finding of Gao and Wu (2014), who pointed out that, over the last 50 years, with the exception of a few regions in NC, SPA and SPD display a decreasing trend to the east of China.

To complete the analysis performed at each individual station over China over the last five decades, we also investigated climate tendency in eight regions of China. Figure 5 shows regional trends in SPA over the period 1961–2013; these regions are NWC, NC, Northeast China (NEC), SWC1, CC, EC, SWC2 and SC, as well as China as a whole. The climate tendency of these eight regions in China are estimated to be 0.10, -3.80 , -0.40 , -0.40 , -0.80 , -1.10 , -1.80 and -0.90

mm/10a, respectively. We found that the most pronounced decreasing trends for SPA occur over EC, SC and SWC2, whereas the trend is weaker over CC, NC, NEC and SWC1. For seven regions of eight, except NWC, the climate tendency is statistically significant. Only the climate tendency over the NWC region ($p = .57, >.05$) is positive and not significant. The climate tendency in China, on average, is estimated to be -0.62 mm/10a, and the decreasing rate reaches 0.33% per year.

We subsequently documented the different climate tendency between SP and TP. The trend in SPA showed a significant decreasing trend in most regions of China, while TPA remained almost unchanged over the past 53 year (see Figures 5 and S3a). The average rate of decrease in SPA is up 0.33% per year, while it was only 0.002% per year for TPA for the whole of Mainland China. Moreover, we figured out that there was 20.6-day decrease for TPD and 17.1-day decrease for SPD over the past five decades (as shown in Figure S3b, c), which indicates a significant decreasing trend for both TPD and SPD. We infer from these numbers that most of the decrease of TPD is attributable to the SPD decrease.

3.1.2 SP variation for different seasons

Table 2 indicates the SP trends in the eight regions of China over the last five decades, for different seasons. As shown in previous studies, e.g. Chen and Lu (1981), climate in China can be fundamentally divided into a monsoon climate and a non-monsoon climate. The latter is mainly represented by the sub-region NWC (Northwest China), and the former is consist of the rest seven regions in this research. The number of stations showing significant decrease trend in NWC is much lower than over any other areas that is dominated by the summer monsoon (see Table 2) in all seasons except JJA. Therefore, we found that the decrease trend of SP in non-monsoon region is the most indistinct during most time of the year, compared with that in monsoon region. (The detailed pattern and seasonal evolution of SP can be found in SI, Figure S4 and S5).

From Table 3, we also derived that most stations show a significant decreasing trend in SON, for both SPA (364 stations, 49.5%) and SPD (505 stations, 68.7%). The number of stations in JJA comes second; there are 222 (30.2%) and 392 (53.3%) stations for SPA and SPD, respectively. The significant decreasing trend is less popular in MAM (SPA: 19.7%, SPD: 41.4%) and DJF (SPA: 25.6%, SPD: 43.1%). Therefore, we concluded that the amount of stations with a significant negative trend tended to occur more in JJA and SON than in MMA and DJF, both for SPA and SPD. The seasonal variation in the trends of both SPA and SPD appear to be related to prevailing meteorological conditions. As precipitation in China is mostly monsoon-driven, in SON, the rainy season has ceased over major regions in China, except for SC and EC. Cold air in NC is powerful during this period, and the southward cold air forces the warm and moist air over land to

retreat to the south. Furthermore, temperature drops sharply in DJF, and evaporation decreases (Miao and Wang, 2007). Weak winter precipitation and evaporation could be the cause for fewer sites with significant variation trends in SP.

The seasonal variation in the trends of both SPA and SPD appear to be related to prevailing meteorological conditions. As precipitation in China is mostly monsoon-driven, in SON, the rainy season has ceased over major regions in China, except for SC and EC. Cold air in NC is powerful during this period, and the southward cold air forces the warm and moist air over land to retreat to the south. Furthermore, temperature drops sharply in DJF, and evaporation decreases (Miao and Wang, 2007). Weak winter precipitation and evaporation could be the cause for fewer sites with significant variation trends in SP.

3.1.3 Daily variation of SP

The median amount of daily SP shows almost no change. As can be seen from Figure 6, it is close to 0.3 mm/day in all eight regions, as well as over the whole of China. This median value indicates that the daily SPA has been kept stable over the past 53 years. Considering that there is an obvious decreasing trend of SP amount over the 53 years under study, we attribute this decrease to a decrease in the number of SP days.

3.2 The relationship between slight precipitation and AVHRR NDVI during growing season

We also documented the multiyear trend for NDVI in eight regions and the whole of China, as shown in Figure S6. NDVI trends are generally decreasing as SP does but not in NC and NEC. Therefore, we further performed a spatial correlation for SP and NDVI for different regions and different vegetation types.

3.2.1 Correlation between SP and AVHRR NDVI for different regions

In this section, we investigate the correlation between NDVI and SP in the eight regions over China. The spatial pattern of NDVI/SPD is highly consistent with that of NDVI/SPA (as shown in Figure 7). The correlation coefficient between SP and NDVI generally ranges from -0.33 to 0.51 . There are positive values in the north of China, including NEC, NC and NWC, with values ranging from 0.00 to 0.51 . In contrast, the correlation coefficient values in the other five regions are negative and range from -0.33 to 0.00 .

The spatial distribution of the correlation coefficients between SP and NDVI shown in Figure 7 exhibits a progressive increasing trend from southeast China to NWC. This may be due to a more abundant precipitation condition over

southeast China than over NWC, consistent with our previous speculation. This result suggests that the growing environment for the plant is one of the most important factors affecting the correlation coefficient between SP and NDVI. The maximum value (> 0.35) can be found in the west of NEC and the north region of NWC, while the minimum value (< 0) appears in the south region of China. TP (see Figure S2) within NEC, NC and NWC are at a similar level (< 600 mm/year, relatively less in China), and the long-term correlation coefficients in these regions are positive. Concerning regions with higher TP (> 600 mm/year), the correlation coefficients showed an opposite trend but were not statically significant, and we interpreted it as an indication that there are other causes for variability of these regions. The spatial patterns of extreme value in the correlation coefficient of NDVI/SPD and TP are almost distinct to each other, which means the regions with more precipitations tend to display less correlation coefficients of NDVI/SPA and NDVI/SPD. This may be because that SP does not play a key role on the growing of vegetation in regions with abundant precipitations. In contrast, SP is a necessity for plants growing in arid areas, like NWC, NEC and parts of NC. The local differences between the correlation coefficient of NDVI/SPA and NDVI/SPD are illustrated by the shadowed areas (statistically significant at the 95% [$p < .05$] level) in Figure 7. Shadow areas in Figure 7b spread over a larger surface than that in Figure 7a. Thus, we infer that SPD has stronger effects on the growth of natural vegetation compared with SPA.

3.2.2 Correlation between SP and AVHRR NDVI for different vegetation types

We investigate the correlation between SP and NDVI for different natural vegetation types (Alpine Vegetation and Mixed Needle leaf and Broad-leaf Forest, covering no monitoring stations, were discarded). There is no significant difference between the correlation coefficients of NDVI and SPA and that of NDVI and SPD. Table 4 shows that the maximum NDVI/SP correlation coefficient occurs six times with SPD and only two times with SPA. This suggests that the degree of correlation between natural vegetation's NDVI and precipitation days is higher than with precipitation amount. The correlation coefficient of NDVI/SPD is also relatively higher than that of NDVI/SPA, as mentioned in section 3.2.1.

In addition, we also found that SPA and SPD have lag effects on some kinds of vegetation. For example, coniferous forest, grassland, grass cluster and marsh, and the maximum correlation between NDVI and SP appears to be better correlated with a 1-month or 2-months lag, rather than no lag (Table 4).

Reclassifying the vegetation into five types as shown in Figure 8 shows that the correlation coefficient between herbaceous vegetation NDVI and SP is the highest (only consider the three most common type of vegetation, herbage, trees and shrub here), trees come second, and the least correlated vegetation type appears to be shrubs. This may be

associated with the growing properties of the plant itself, including root system. The roots of shrub vegetation and trees tend to extend deep into the soil, and their sensitivity to SP is much lower than herbaceous vegetation, the roots of which have a relatively shallow extent. Besides, the correlation coefficient between NDVI of desert vegetation and SP (both SPA and SPD) is higher than for any other type of vegetation. We speculate that the growing condition of plants is also of great importance to the correlation coefficient of NDVI/SP. SP is not a vital factor for plants that grow in areas with frequent rainfall, and thus, the correlation coefficient between SP and NDVI is relatively low. On the contrary, for desert plants, they are more dependent on precipitation at small levels. Thus, their sensitivity to SP is more intense.

We are now proposing several future directions to explain the decreasing trend quantified in SP here over China. Qian et al. (2009) discussed the role of human activities in the decrease of SPA and SPD over EC. Gao and Wu (2014) argued that this trend was driven through the relationship between SP and aerosol abundances retrieved through aerosol optical depth. The microphysical interactions between aerosol and clouds are likely to cause this behaviour. Many studies point to the role of modulating the NDVI (Al-Bakri and Suleiman, 2004). Understanding this link will require sorting out the respective roles of meteorological factors, root zone soil moisture and soil physical properties (Cihlar et al., 1991; Schultz and Halpert, 1993). In addition, although the correlation coefficient of NDVI/SP was documented over the last five decades here, at a national scale, we cannot predict how its decreasing trend affects the natural vegetation growth. Such relationships between natural vegetation and SP require a suitable model that includes the effects of SP on plant phenology.

4. Conclusions

This study documents the temporal and spatial SP variation over China and determines the trends of SP by season over the last five decades. Temporal variations of SPA and SPD both show a negative trend from 1961 to 2013, which is in agreement with TP, although at a different speed. It shows seasonal and regional differences as well. Moreover, we identified that the decrease of SPD plays a more important role on the decrease of SP, compared with SPA. Despite the spatio-temporal variation of SP, we also explored the relationship between SP and NDVI during growing season by investigating the correlations between SP and NDVI of various vegetation types. We found that these correlation coefficients between NDVI and SP are stronger in regions with less TP, mainly distributed in desert vegetation. Over these regions, SP has a key influence on the growing condition of vegetation. In addition, SP has the most significant influence on NDVI from the desert, followed by grass and marsh. It has no significant effect on tree or shrub from our results. The relationship between SP and NDVI provides us with new insights on the dependence of natural vegetation

growth on meteorological factors, and people should pay more attention on SP, especially in arid and semi-arid areas.

Acknowledgment

This study was supported by the National Natural Science Foundation of China (Grand No. 41771495) and by the 111 project of the Ministry of Education of China (B14001). The authors are grateful to Haibo Du for his technical support.

Marsh (h)	3	-0.20*	-0.16	0.18	0.30**	0.08	0.10

FIGURE 1 Geographical distribution of the 735 MS adopted in this research and domains of eight sub regions in China--NEC: Northeast China; NC: North China; EC: East China; CC: Central China; SC; NWC: Northwest China and Southwest China are marked by SWC1, and SWC2, respectively. Together they are called Southwest China. CN refers to China as a whole. The line in red named Heihe-Tengchong line (It is also called Hu line). Heihe is a city in Northeast China, and Tengchong is in Southwest China.

FIGURE 2 Distribution of slight precipitation amount (SPA) (panel a) and slight precipitation days (SPD) (panel b) in 53 years (1961 - 2013), the areas in dark colour display a high value in SPA and SPD, and the light colour show low values. These isolines functioned as labels of gradient for understanding quantitatively.

FIGURE 3 Time series of annual SPA (a), SPD (b) and their 3-year moving average from 1963 to 2013.

FIGURE 4 Spatial distribution of trend for annual SPA (a) and SPD (b) during the period of 1961-2013. The monitoring stations coloured in red and blue represent a positive and negative trend, respectively. The stations trend indicators shown as bigger blue dots are significant at the 95% confidence level. The black line is Heihe-Tengchong line.

FIGURE 5 Trends of SPA in eight regions and in whole China from 1961 to 2013. The blue scattered points represent annual SPA. The red and black lines show the linear tendency of each area (Red lines ($p < 0.05$) represent statistical significant, while black line ($p > 0.05$) does not). P-value of linear fit can be checked in table S3, row SPA.

FIGURE 6 Median value of daily SP against year. The blue scattered points represent the median value of daily SP within one year with the record of slight precipitation.

FIGURE 7 The correlation coefficient of NDVI/SP in different regions over China, and a,b presented NDVI/SPA and NDVI/SPD (ensemble-average result from 1981 to 2006), respectively. The regions covered with shadow indicates statistically significant at the 95% ($P < 0.05$) level.

FIGURE 8 Correlation coefficients between SP and NDVI: (a) SPA and NDVI, (b) SPD and NDVI. Asterisk (*) indicates statistically significant at the 95% ($P < 0.05$) level, ** indicates statistically significant at 99% ($P < 0.01$) level.
