Abstract

We analyzed litter occurrence in 68 underwater video transects performed on the middle/outer continental shelf and submarine canyon off Cap de Creus (NW Mediterranean), an area recently declared Site of Community Importance (SCI). Low densities of urban litter were registered on the shelf ($7.2 \text{ items ha}^{-1}$), increasing in abundance towards the deepest part of the submarine canyon, with $188 \text{ items ha}^{-1}$ below 1000 m depth. We hypothesize that the strong bottom currents that recurrently affect this area efficiently move litter objects from the shelf towards the deep. Of all litter items, approximately 50% had a fishing-related origin, mostly longlines entangled on rocks in the canyon head and discarded trawl nets in deeper areas. Over 10% of cold-water colonies observed had longlines entangled, indicating the harmful effects of such practices over benthic habitats. These results should be considered when designing mitigation measures to reduce litter pollution in Cap de Creus SCI.

Keywords: plastics, funneling, litter hotspots, longlines, cold-water corals, continental margin

1. Introduction

The widespread distribution of materials produced by human societies that get stranded ashore or reach the seabed is now considered a critical issue in terms of marine conservation (Galgani et al., 2015, Rangel-Buitrago et al., 2020). Its presence in all parts of the ocean has alerted national and international authorities, researchers and stakeholders worldwide, which

foresee the consequences of not properly addressing this issue in the forthcoming years (UNEP, 2009; Agamuthu et al., 2019). The vast majority of discarded items are primarily made of plastic or have plastic components (Jambeck et al., 2015; Beaumont et al., 2019), mainly due to its low manufacturing cost and its durability. This property also makes plastic extremely dangerous, since it can last for decades once discarded (Laist, 1987). After plastic items have reached the marine environment, measures to retrieve them are complex and expensive, especially with increasing depths (Iñiguez et al., 2016). Besides the aesthetic, health and economic problems derived from the accumulation of human-derived objects in the marine environment, litter is steadily becoming a serious threat to wildlife, since it can kill or harm all sorts of marine organisms, from algae to birds (Kühn et al., 2015). The list of deleterious effects caused over marine fauna is extensive, and includes among others the entanglement or smothering of sessile animals (Yoshikawa and Asoh, 2004) and the ingestion of fragmented litter by heterotrophic organisms (e.g. Courtenes-Jones et al., 2018). Recent studies have documented the ingestion of microplastics by commercially important deep-sea species (Carreras-Colom et al., 2018; Cau et al., 2019), indicating the great implications that its accumulation may have for the marine ecosystem and also for human health.

In European seas, around 30% of all marine litter that accumulates on shelf, slope and canyon habitats can be attributed to abandoned, lost, or discarded fishing gear (ALDFG; Pham et al., 2014b), although this percentage can reach 50-80% in traditional fishing grounds, such as Campania, Sicily or Liguria (Angiolillo et al., 2015; Consoli et al., 2018; Enrichetti et al., 2020). These high

1 percentages may be explained by the increase of the fishing effort during the
2 past decades and a steady transition to synthetic and more durable materials
3 to manufacture fishing nets and lines (Gilman et al., 2016), which lead to an
4 increased likelihood of gear loss (Richardson et al., 2019). The remaining litter
5 items observed over the seabed derive from a wide range of sources, yet
6 most of them consist partially or entirely of plastic (Pham et al., 2014b;
7 García-Rivera et al., 2018). It is now becoming very common to find plastic
8 bottles, plastic bags and clothes half buried in the sediment or entangled
9 around rocks in deep water environments (van den Beld et al., 2017; Moriarty
10 et al., 2016). In the Mediterranean Sea, studies performed over the
11 continental margin have found litter items in almost all surveyed sites
12 (Angiolillo et al., 2015; Pasquini et al., 2016; García-Rivera et al., 2018;
13 Gerigny et al., 2019; Enrichetti et al., 2020). Highest densities are generally
14 registered in areas close to shore or immediately adjacent to large cities
15 (Strafella et al., 2019; Buhl-Mortensen and Buhl-Mortensen, 2017), with
16 accumulation areas (“litter hotspots”) also observed at bathyal depths, either
17 inside submarine canyons or following the path of the main oceanic currents
18 (Tubau et al.; 2015; Cau et al., 2018; Pierdomenico et al., 2019).

19 Aiming to minimize the effects produced by human-derived objects in the
20 marine environment, the European Commission included marine litter in the
21 Marine Strategy Framework Directive (MSFD) as one of the 11 descriptors to
22 be considered when assessing the achievement of ‘Good Environmental
23 Status’ (GES) of European seas (Council of the European Union, 2008). The
24 MSFD provides the legal framework to encourage Member States to report
25 and subsequently monitor the abundance of marine litter in their territorial
26

1 waters, leading to the implementation of area-specific management measures
2 to reduce the amount of litter that reaches the marine environment, and
3
4 designing specific actions to minimize land-based sources when possible
5
6 (Galgani et al., 2013). The application of such measures, however, must be
7
8 based upon a comprehensive knowledge of the actual composition,
9
10 abundance and spatial distribution of marine litter in each area.
11
12

13
14 The continental shelf and the submarine canyon off Cap de Creus currently
15
16 belong to a Site of Community Importance (SCI) of the Natura 2000 Network
17
18 (BOE, 2014). Following the demands of the MSFD, the implementation of an
19
20 ecosystem-based approach to manage human activities in Cap de Creus
21
22 marine area requires a thorough evaluation of the amount of litter items that
23
24 can be found in its shelf and canyon habitats. Making use of 68 underwater
25
26 video dives performed between 80 and 1570 m depth prior to the declaration
27
28 of the SCI, this paper aims to (1) evaluate the quantity and spatial distribution
29
30 of marine litter on the Cap de Creus continental shelf and submarine canyon,
31
32 (2) identify the main causes of such distribution, and (3) assess the potential
33
34 impacts of ALDFG over the three main cold-water coral species dwelling in
35
36 the submarine canyon, namely *Madrepora oculata*, *Lophelia pertusa* and
37
38 *Dendrophyllia cornigera*.

prominent role in the hydrological and sediment dynamics of the whole margin (Canals et al., 2004). The Rhône River supplies most of the terrigenous input to the gulf, with an average of more than 6.5 Mt of suspended particulate matter discharged every year (Poulier et al., 2019). Most of the sediment remains stored on the shelf until specific atmospheric situations trigger high-energy oceanographic events such as dense shelf water cascading and sea storms that are able to resuspend and transport large quantities of sediment, organic matter and pollutants to the deep, mainly along submarine canyons (Canals et al., 2006; Palanques et al., 2006; Salvadó et al., 2012, 2017).

Cap de Creus Canyon is located at the southernmost end of the Gulf of Lion shelf. The canyon head is just 4 km ahead of Cap de Creus promontory and is deeply incised on the continental shelf at 125 m depth (Figure 1; Lastras et al., 2007). Because of its location at the southern exit of the dominant circulation pattern in the Gulf of Lion, and also because of the obstacle effect of the promontory that deviates offshore coastal and shelf currents, Cap de Creus Canyon behaves as the preferential conduit of water and sediment from the gulf's shelf to the deep margin and basin (Canals et al., 2006; Palanques et al., 2006). The presence of strong bottom currents and the supply of large quantities of organic material favors the development of rich benthic communities, both on the continental shelf and the submarine canyon (Dominguez-Carrió, 2018), where dense patches of cold-water corals, mainly *Madrepora oculata*, have been observed (Orejas et al., 2009).

Most of Cap de Creus peninsula was declared a maritime-terrestrial Natural Park in 1998, including a narrow shallow water peripheral belt of the innermost continental shelf (mostly infralittoral stage) (BOE, 1998). It was in

2014 when a large part of the continental shelf and the submarine canyon was included in the Site of Community Importance “South-West Gulf of Lion canyons system”, as part of the Natura 2000 Network of protected areas of the European Union (Area ESZZ16001; BOE, 2014).

2.2. Video surveys and imagery analysis

The extensive dataset used in this study was obtained from 68 underwater dives performed during 5 oceanographic cruises between 2007 and 2013, as part of the HERMES, DEEP CORAL, PROMARES and Life+ INDEMARES projects. Four different underwater vehicles were used: the manned submersible JAGO (GEOMAR, Germany), the commercial ROV Liropus 2000 (IEO, Spain), the purpose built ROV Nemo (Gavin Newman, UK) and the small and compact ROV Bleeper EVO (ICM-CSIC, Spain). All vehicles but Bleeper EVO were equipped with an HD camera and a USBL system to obtain accurate positions of the vehicle over the seabed, with a time frequency below 20 seconds. Bleeper EVO, which was only used on the continental shelf, had an SD definition camera and its position was inferred from that of the vessel and the angle of the cable when being towed over the seafloor. Geographic positioning data was used to calculate the distance travelled by the underwater vehicle in each dive. All platforms were equipped with parallel lasers to provide scale to the images. Metadata regarding each dive is provided in Table 1, with reference to the video platform used. Data obtained during the PROMARES cruise (dives 37 to 44) was partly published in Tubau et al. (2015), and considered in this study given its relevance to better determine spatial patterns in litter distribution along Cap de Creus submarine canyon.

1 All underwater dives were performed from the mid and outer continental shelf
2 (80-90 m water depth) down to the submarine canyon floor at 1600 m (Figure
3 1; Table 1). Dive length was extremely variable (from 80 m to 3 km) and
4 dependent on weather conditions, underwater visibility and bottom current
5 speed. The total seafloor distance covered was 47.5 km, which represents an
6 area visually examined of about 7.5 ha. All transects were performed as
7 straight as possible while keeping a constant speed above ground of $0.3 \text{ m}\cdot\text{s}^{-1}$
8 in average.
9

10 Final Cut Pro 7 (Apple Inc.) video editing software was used to remove the
11 time intervals when the underwater vehicle stayed stationary, so multiple
12 counting of the same item was avoided. Those sections with poor image
13 quality, mostly due to sediment resuspension or excessive distance from the
14 seabed, were also identified and subsequently removed from the statistical
15 analyses. During the PROMARES cruise (dives 37-49), an average field of
16 view (FOV) estimated at 3 m was selected for litter quantification (see details
17 in Tubau et al., 2015). Dives performed with the manned submersible JAGO
18 (dives 1-9 and 32-36) had an estimated average FOV of 2 m. For the
19 remaining transects, which were performed with smaller ROVs that filmed
20 from a closer distance to the seabed, a 50 cm average FOV was chosen to
21 calculate litter density. All human-derived items and cold-water coral colonies
22 of the species *Madrepora oculata*, *Lophelia pertusa* (recently reclassified as
23 *Desmophyllum pertusum*, see Addamo et al., 2016) and *Dendrophyllia*
24 *cornigera* were identified and annotated within the selected field of view in
25 each underwater dive.

58 **2.3. Data treatment**

59
60
61
62
63
64
65

1 Marine litter items were classified in two main categories: (1) ALDFG, which
2 included bottom trawl nets, bottom trawl cables, longlines and trammel nets,
3
4 and (2) urban litter, which was further subdivided in plastic, metal, glass,
5
6 ceramics, clothing (regardless of its fabric), paper and wood. It should be
7
8 noted that all fishing gears and related items, whether made of plastic or
9
10 metal, were all attributed to ALDFG. Making use of transect length (L) and
11
12 width (W), densities for each litter category were calculated at the transect
13
14 level as items per ha⁻¹, simply dividing the number of items by the area
15
16 explored in each dive ($De = \text{items} / L \cdot W$).
17
18
19
20

21 To account for spatial and depth variability in the distribution of litter items,
22
23 five domains were defined within the study area in and around Cap de Creus
24
25 Canyon (Figure 1), following those defined by Lastras et al. (2007):
26
27

- 28 1. Northern mid and outer shelf (NS): the continental shelf north of the
29 eastern tip of the cape, from 80 to 150 m depth.
30
31
- 32 2. Southern mid and outer shelf (SS): the continental shelf south of the
33 eastern tip of the cape, also from 80 to 150 m depth
34
35
- 36 3. Canyon head (CH): from the shelf break at a mean depth of 150 m
37 down to 400 m depth inside the canyon.
38
39
- 40 4. Upper canyon (UC): between 400 and 1000 m depth.
41
42
- 43 5. Middle canyon (MC): between 1000 and 1600 m depth.
44
45
46
47

48 The impact of ALDFG on the above-mentioned cold-water coral species was
49 assessed by calculating the percentage of entangled colonies of each species
50
51 along selected underwater dives (1-9) carried out in the canyon head, from
52
53 160 to 390 m depth.
54
55
56
57

58 **2.4. Modelling the bottom currents**

59
60
61
62
63
64
65

1 The free surface, generalized sigma vertical coordinate, 3D hydrodynamic
2 model SYMPHONIE described by Marsaleix et al. (2006, 2008, 2012) was
3
4 used to calculate the bottom currents in the study area. This model classically
5
6 solves the equations for temperature, salinity and the two components of
7
8 horizontal current starting from initial conditions and using time-dependent
9
10 forcing. The horizontal grid was designed to study the connections between
11
12 the Gulf of Lions and the Catalan region with the south of the basin through
13
14 the formation and dispersion of dense water. The resulting curvilinear grid had
15
16 a pole positioned in the Pyrenees, allowing a minimum resolution of about 700
17
18 m near the French and Catalan coast, and increasing to reach 5-6 km near

64
65

The model was initialized and forced at its open boundaries by the NEMOMED8 model described in Herrmann et al. (2010). At the surface, the same atmospheric forcing than this model was used i.e. the ARPERA dataset (Herrmann and Somot, 2008), which is a dynamic downscaling of the ERA40 climate model reanalysis (1976-2001) and of the ECMWF (European Centre for Medium-Range Weather Forecasts) model reanalysis since 2001. This forcing consists in daily averaged wind stress, solar flux, long wave net heat flux, sensible and latent heat flux and precipitation, leaving the diurnal cycle unresolved. The sea surface temperature was nudged towards the climatological one used in the NEMOMED8 model, ensuring the consistency between the two models. The two components of the horizontal current were then extracted from the daily outputs of the model, rotated to be along the WE and NS axis and interpolated on a regular grid. The simulations were run from the beginning of year 2000 to the end of 2013, and the daily currents for the

1 month of February 2012 were averaged to illustrate the strength of bottom
2 currents in the area. This month was chosen because it is known to be an
3 exceptional period of dense water formation on the Gulf of Lion shelf, with
4 deep cascading in Cap de Creus Canyon (Durrieu de Madron et al., 2013;
5 Sanchez-Vidal et al., 2015), a recurrent process known to occur periodically in
6 the area. Although extreme deep-cascade events are not very frequent (high-
7 intensity events recorded in 1999, 2005 and 2012; e.g. Canals et al., 2006;
8 Ulses et al., 2008; Durrieu de Madron et al., 2013), Mikolajczak et al. (2020)
9 estimated that during the period 2010-2017, one year out of two, cascading
10 could affect depths of 1000 m, while in the remaining years it would only
11 sporadically reach 500 m depth.

29 **3. Results**

30 **3.1. Composition of marine litter**

31 In total, 833 litter items were identified in the video images recorded on the
32 continental shelf and submarine canyon off Cap de Creus. This corresponds
33 to an average density of 110 items ha⁻¹ for the entire study area (80-1600 m
34 depth). The number of items and density per dive, organized in the different
35 litter categories, is provided in the Supplementary Table 1.
36
37
38
39
40
41
42
43
44
45

46 There were 394 urban litter items (47% of the total), which appeared in 30%
47 of the dives (Table 1). A wide variety of objects could be identified, including
48 plastic and glass bottles, shopping bags, tin cans and clothes of different sorts
49 (examples in Figure 2a-c). Very few items reached large sizes (>1m) besides
50 some car tires and an oil drum (Figure 2d,e). The abundance of urban litter
51 was generally low across dives, although density values exceeded 100 items

ha⁻¹ in 4 transects (8-26-39-40). Plastic was the main component, with almost 80% of all urban litter objects completely made of plastic or included plastic parts. Six amphorae were also identified in the footage (Figure 2f).

About 53% of the total number of litter items (439) were classified as abandoned, lost or otherwise discarded fishing gears (ALDFG). The vast majority corresponded to longlines, with 371 items (85% of ALDFG; examples in Figure 2g,h). The number of bottom trawl nets and cables was much lower (56 items, 13%; examples in Figure 2i,j), and trammel nets were the least common type of fishing gear, with only 12 items observed (3% of all ALDFG; examples in Figure 2k,l).

3.2. Spatial and depth distribution

Mid and outer continental shelf. Urban litter items were not commonly observed on the videos registered on the continental shelf, with only 14 items annotated in 1.93 ha explored. This represents an average density of 7.2 items ha⁻¹ for the continental shelf, with recorded densities slightly higher on the northern side (Figure 3), although no clear pattern could be determined (Figure 4a). Plastic objects and objects with plastic components constituted around 38% of all reported urban litter (5 items), with densities below 4 items ha⁻¹ on both shelves. Glass was the second most common category, with 4 items (30%). Litter objects made of other materials, like metal (8%), ceramics (15%) and textiles (15%), appeared in lower numbers, and no items made of wood and paper were reported. Densities of ALDFG were similar on both sides of the continental shelf (Figure 3), with slightly higher densities on the southern (59.5 items ha⁻¹) than on the northern side (45.6 items ha⁻¹). Most

1 ALDFG items were registered along the 100 m isobath north and east of the
2 easternmost part of the cape (Figure 4b), where rocky outcrops and mixed
3 substrates were generally observed in the images. Longlines were by far the
4 most common type of ALDFG found on the continental shelf, accounting for
5 76% of all fishing-related items. With 79 longlines reported (NS: 33; SS: 46),
6 densities on both sides stayed around 40 items ha⁻¹ (Figure 3). Trammel nets
7 appeared only on the southern side (12% of ALDFG, 10.5 items ha⁻¹),
8 generally entangled over small and medium sized rocks (Figure 2k). Bottom
9 trawl nets and cables represented 13% of all ALDFG, with most nets
10 appearing on the southern shelf (NS: 3; SS: 10), where their density was
11 around 8.7 items ha⁻¹ (Figure 3, examples in Figure 2i,j)

12 *Canyon head.* 28 urban litter items were identified on the 1.33 ha explored,
13 corresponding to a density of 21.1 items ha⁻¹ (Figure 3). Per material types,
14 51% of urban items were made of metal (11.3 items ha⁻¹) and 24% of plastic
15 (5.3 items ha⁻¹). The number of glass and clothing items was almost
16 negligible. Most of the amphorae observed in the footage (4) were reported in
17 the canyon head. ALDFG reached maximum values in this domain (323
18 items), with a density of 243.6 items ha⁻¹ (Figure 3). All but 3 dives performed
19 in the canyon head contained remains of ALDFG, with some dives reaching
20 local densities above 500 items ha⁻¹, particularly on the westernmost part of
21 the canyon head (Figure 4b). More than 80% of all ALDFG identified
22 corresponded to longlines (290 items), which represents a density of 218.7
23 lines ha⁻¹ (Figure 3, examples in Figure 2g,h). It should be noted that
24 according to the tradition in the area and the design of longlines and trammel
25 nets, these two techniques are not practiced in areas deeper than 400 m.

Parts of bottom trawl nets also reached here the highest numbers of any domain (33 trawl nets and ropes, 24.9 items ha⁻¹), and were mostly observed as thick pulling ropes, especially in dive 42.

Upper canyon. Urban litter items were much more abundant in the upper canyon than in the previous two domains combined, with 122 items identified in the 3 ha explored, resulting in a density of 39.5 items ha⁻¹ (Figure 3). Most objects were made or had plastic components (76%, 30.1 items ha⁻¹), with a smaller fraction made of metal items (18%, 7.1 items ha⁻¹). Other materials were represented by objects made of wood, ceramics, glass and paper, all of them with densities lower than 1 item ha⁻¹. The abundance of ALDFG decreased significantly below 400 m depth, with only 7 fishing-derived items identified in the upper canyon (2.3 items ha⁻¹; Figure 3). All ALDFG in this depth range had a bottom-trawl origin, with most items being actual trawl nets (5) and pulling ropes (2) (Figure 5a).

Middle canyon. With 230 objects identified in the 1.2 ha explored, the highest number of urban litter items of any domain corresponded to the middle canyon (187.8 items ha⁻¹; Figure 3). This represents 58.4% of urban litter items identified in the whole video footage. The largest fraction corresponded to items made of plastic, a material appearing in almost 90% of the urban items reported in this domain. In contrast, metal objects accounted for only 6% (11.4 items ha⁻¹), whilst the remaining categories contributed with less than 1-3% each (Figure 3). In some specific areas at around 1200 m depth (Dive 40), there existed accumulations of several litter objects in a build-up appearance, forming what can be considered “litter hotspots”, where some aged items were observed half buried under the sediment (example in Figure

5b). Regarding ALDFG, 2 longlines and 3 bottom trawl nets were identified in the middle canyon, where an overall density of 4.1 items ha⁻¹ was reported (Figure 3). It should be noted that bottom trawling is not usually practiced in Cap de Creus at depths below 800 m.

3.3. Bottom currents

Bottom current speed and direction averaged for the month of February 2012 after applying a bilinear interpolation to the modelled data (gridded at 700x700 m cells) is shown in Figure 6. As shown by the model, after a very intense cascading event, coastal waters can reach the base of the slope, at depths in excess of 1500 m. Bottom currents associated with this process are gravity currents whose intensity is proportional to the bathymetric slope. The acceleration of the current at the end of the shelf, first between 100 and 200 m depth, and then beyond 200 m inside the canyon, can generate flow velocities above 1 m s⁻¹. Highest current speeds are found on the southern part of the canyon head and the upper canyon, where the dense water vein penetrates with a significant angle of incidence with respect to the isobaths. Further downstream, under the action of the Coriolis force that deflects the current to the right, the dense water vein is progressively flattened along the southern flank of the canyon, which produces a decrease of the current strength. Currents of up to 30 cm s⁻¹ are also present on the external part of shelf, corresponding to water masses less dense than those that penetrate in the canyon. Regarding the realism of the simulation, currents above 1 m s⁻¹ were measured in February 2012 at depths of 1000 m in the canyon axis, with a current meter located 23 m above the seafloor (Sanchez-Vidal et al., 2015).

1 This would indicate that the results shown here could be underestimating the
2 maximum current speeds that can be reached during cascading events.
3

4 **3.4. Interaction of litter with cold-water corals and other sessile fauna**

5
6
7 A total of 335 colonies of cold-water corals were identified in the canyon head,
8
9 of which 302 *Madrepora oculata*, 26 *Dendrophyllia cornigera* and 7 *Lophelia*
10
11 *pertusa*. Besides some variability at transect level, and independently of the
12
13 species, more than 10% of the colonies had on average entangled longlines
14
15 around them (Table 2). In most cases, longlines were observed hooked
16
17 around the branches of the cold-water corals, regardless of the species
18
19 (Figure 7). In general, most corals seemed to remain alive when having
20
21 cables twisted around them. However, the distance of the camera to the
22
23 colonies did not allow for a closer examination to determine the percentage of
24
25 polyps affected and the level of harm produced. It was also impossible to
26
27 determine how many broken branches resulted from the interaction between
28
29 longlines and the coral colonies.
30
31
32
33
34
35

36
37 Some of the thickest longlines were also observed to act as substrate for
38
39 several sessile species to live on, although for some of them precise
40
41 identification was certainly difficult. Most species were bushy hydrozoans and
42
43 bryozoans, together with the abundant polychaete *Sabella pavonina*, which
44
45 was commonly observed attached to lines suspended over the seafloor
46
47 (Figure 7c). Besides the effects produced by longlines on cold-water corals,
48
49 other fishing gears were also observed to interact with benthic and demersal
50
51 fauna. As an example, a large trammel net was found fully extended over the
52
53 soft bottoms of the southern continental shelf (Dive 34; Figure 2l). As
54
55 observed in the images, this net had at least two large spiny lobsters

(*Palinurus elephas*) caught in it, one of which still alive, as well as other dead fishes impossible to identify. Also on the southern shelf, a large bottom trawl net was found lying over a sand plain with small outcropping rocks (Dive 36; Figure 2i). This trawl net was covered by a large number of small organisms (several species of sponges, ophiuroids and holothurians), indicating that it might have been lost for some years. Inside the submarine canyon, litter hotspots were generally observed over soft-bottom areas (Figure 5). Although the level of interaction was not quantified, the presence of these deposits seemed to overlap with the distribution of burrowing megafauna, including the anemone *Cerianthus membranaceus* (Figure 5a).

4. Discussion

4.1. Seafloor litter provenance, abundance and distribution

The popularity of Cap de Creus as a touristic attraction, with a significant increase in tourism and recreational boating during summer months (Lloret et al., 2008), and the historical relevance of its fishing grounds (Lloret and Riera, 2008), might help explain the amount and variety of litter objects encountered on its shelf and submarine canyon. Plastic was by far (80%) the most common material that made up urban litter items. This situation is similar to that encountered in most shelf and slope environments of the European continent, both in the Atlantic (e.g. Neves et al., 2015; Moriarty et al., 2016; van den Beld et al., 2017; Maes et al., 2018) and the Mediterranean Sea (e.g. García-Rivera et al., 2018; Gerigny et al., 2019; Spedicato et al., 2019). Most items were small sized, and included plastic bags and bottles, but also clothes and other daily use objects. These items were possibly brought from

1 surrounding areas by the wind or terrestrial run-off mainly during torrential
2 events (Rech et al., 2014), or even discarded directly on beaches or at sea
3
4 (Tubau et al., 2015). However, due to the particularities of the Gulf of Lion, the
5 likelihood of an allochthonous origin of at least part of the lighter fraction
6
7 should not be ruled out, with items reaching the sea from rivers that discharge
8
9 in other parts of the gulf (Castro-Jiménez et al., 2019) and transported
10 following the dominant water circulation patten (Millot, 1990). Conversely, the
11 presence of some very large items such as fuel drums and car tires are an
12 indication of intentional dumping, likely from the side or the back of vessels, a
13 practice already identified in other areas of Europe's seas (e.g. Mordecai et
14 al., 2011; Strafella et al., 2015). Although it is difficult to determine how long
15 these objects have been at the seafloor, their presence might relate to
16 practices that were more common in past decades, when the legislation on
17 ocean dumping was less restrictive and the collection of waste by port
18 authorities was not as widespread as it is nowadays (MARPOL, 1988).

22
23
24
25
26
27
28
29
30
31
32
33
34
35
36 The overall density of 110 litter items ha⁻¹ registered in Cap de Creus is of a
37 similar magnitude to that found in the close-by submarine canyon of La
38 Fонера, located only 50 km south (150 items ha⁻¹; Tubau et al., 2015).
39 However, imaging studies carried in other shelf and upper slope areas of the
40 Mediterranean have reported litter densities up to one order of magnitude
41 higher than those found in Cap de Creus, for example in the Ligurian basin
42 (1500 items ha⁻¹, Enrichetti et al., 2020 and Bo et al., 2014) and the
43 Tyrrhenian Sea (1200 items ha⁻¹, Angiolillo et al., 2015). Such differences
44 must be attributed to the higher number of abandoned fishing gears that can
45 be found on the seabed of the Central Mediterranean, where deep rocky
46

63
64
65

1 banks and submarine canyons are highly frequented by local fishermen (e.g.
2 Angiolillo et al., 2015; Cau et al., 2017; Consoli et al., 2019; Enrichetti et al.,
3 2020). In Cap de Creus, densities of ALDFG peaked at the canyon head (150-
4 400 m), where more than 90% of litter items encountered were fishing-related.
5 This situation was primarily associated to the large number of entangled
6 longlines observed in the images, which generated an average density of 219
7 lines ha⁻¹ for the canyon head. Very high abundances, in excess of 1000 lines
8 ha⁻¹, were reported in some spots, being Dive 9 the most characteristic
9 example, with 119 lines annotated in a transect of less than 500 m in length.
10 This situation seems to relate directly to the artisanal fishery that has been
11 practiced in the area for a long time (Lloret and Riera, 2008), and even though
12 the number of active longlining boats has steadily declined during the past
13 decades (Gómez et al., 2006), its imprint remains visible in the steepest areas
14 of the canyon head. As in Cap de Creus, the presence of lost longlines has
15 become very common in seamounts and submarine canyons worldwide since
16 these gears get easily entangled on hard grounds (Macfadyen et al., 2009;
17 Pham et al., 2013). Lost lines and cables have now been reported in almost
18 all submarine canyons across European continental margins, such as the
19 canyon system of the Gulf of Lion (Fabri et al., 2014; Gerigny et al., 2019), the
20 Bay of Biscay (van den Beld et al., 2016) and those of Portugal (Oliveira et al.,
21 2015). Data comparisons with the remaining submarine canyons of the gulf
22 are not straightforward, since litter abundance in these areas, although
23 collected from ROV images, is expressed in items per linear km. As reported
24 by Fabri et al. (2014), the submarine canyons of the Gulf of Lion had peak
25 values of 4 fishing gears per linear km, most of which concentrated at depths

64
65

1 of 250-350 m. A simple transformation of our data to these units yields 45.5
2 items km⁻¹ for Cap de Creus canyon head (150-400 m depth), a value 11
3
4 times higher than that reported in Lacaze-Duthiers Canyon, where the above-
5 mentioned peak value of Fabri's was encountered. This submarine canyon is
6
7 the closest to Cap de Creus, and the proximity of both canyons to several
8
9 fishing harbors and the high productivity of this part of the gulf may explain
10
11 such large differences between them and the remaining canyons of the gulf.
12
13

14
15
16 Other much less abundant types of fishing gear consisted of a few trammel
17
18 nets, mostly entangled on small rocky outcrops on the flat sandy areas of the
19
20 southern shelf, and some large bottom trawl nets lying on shelf and middle
21
22 canyon soft muddy bottoms. It is in these two domains where most bottom
23
24 trawling takes place eased by soft bottom conditions, allowing medium-sized
25
26 trawlers to easily swipe the seabed. Although accidental entanglement is
27
28 significantly reduced in such environments, with rare rocky outcrops, trammel
29
30 and bottom-trawling nets may represent in some places a significant
31
32 contribution to seafloor ALDFG (Macfadyen et al., 2009).
33
34
35
36
37
38

39 **4.2. Seafloor litter transport**

40
41 Urban litter items showed a very clear spatial distribution pattern, with
42
43 densities rapidly increasing with water depth (Figure 3). The deepest domain
44
45 explored (i.e. the middle canyon, from 1000 to 1600 m depth) was the one
46
47 showing the highest density of urban litter items (188 items ha⁻¹), 25 times
48
49 higher than on the mid and outer continental shelf (7.2 items ha⁻¹; see Section
50
51 3.2). A similar situation has been described in other deep-sea areas of the
52
53 Mediterranean Sea, where large accumulations of debris appears below
54
55 1300-1500 m depth, such as the submarine canyons in the Messina Strait
56
57
58
59
60
61
62
63
64
65

1 (Pierdomenico et al., 2019) or the abyssal plains of the Sardinian margin (Cau
2 et al., 2018).

3
4 Beyond the topographic trap effect driven by gravity of submarine canyons,
5 the litter distribution observed in Cap de Creus Canyon, with much more
6 urban litter items in distal deeper areas than on the shore-proximal shallower
7 shelf, must be explained by the dynamics of local bottom currents. Evidence
8 indicates that the strong currents that recurrently sweep out the seafloor off
9 Cap de Creus peninsula (Canals et al., 2006; Ulses et al., 2008; Durrieu de
10 Madron et al., 2013) must be the causative process for such an asymmetric
11 distribution, as they have the capability to carry light urban litter items towards
12 the deepest parts of the submarine canyon, which ultimately becomes an
13 accumulation area. Indeed, erosive and tractive features over the continental
14 shelf embracing the Cap de Creus Canyon and on the canyon southern wall
15 and floor have been also related to sediment-laden, strong bottom flows
16 generated by dense shelf water cascading (Canals et al., 2006; Lastras et al.,
17 2007; Puig et al., 2008; Durán et al., 2014; Ribó et al., 2018). *In situ* near
18 bottom (i.e. 30 m above bottom) current speeds within Cap de Creus Canyon
19 measured at the occasion of dense shelf water cascading events during the
20 last two decades illustrate marine litter transport patterns to the deep (Canals
21 et al., 2006; Sanchez-Vidal et al., 2015). Large volumes of dense water form
22 over the continental shelf of the Gulf of Lion when strong, persistent, cold and
23 dry northerly winds enhance heat losses and cool off shelf surface waters,
24 thus increasing their density. The dense shelf water then flows cyclonically
25 over most of the shelf on a southwestwards-oriented regional circulation
26 pattern. Flow lines converge and flow accelerates because of an obstacle

1 effect produced Cap de Creus Peninsula, in the southwestern part of the gulf.
2 The cape deviates the water course seawards, thus flowing down into the
3 canyon head an upper course, also favored by the narrowing of the shelf
4 shoreward of the canyon head (Figure 6). This process has been identified in
5 many locations both in the Mediterranean Sea and the world ocean (Ivanov et
6 al., 2004; Durrieu de Madron et al., 2005; Canals et al., 2009). Amongst the
7 many canyons in the Gulf of Lions and on the North Catalan continental
8 margin, Cap de Creus Canyon is the main outlet for dense shelf water
9 cascading (and everything else that comes with), which is undoubtedly
10 favored by its location with respect to the regional circulation ahead of the
11 promontory formed by the Cap de Creus Peninsula (Canals et al., 2006). The
12 erosional, tractive and depositional effects of these cascades on the canyon
13 floor are clearly visible down to its mouth at 2140 m depth and beyond are
14 illustrated by giant furrows, an incised thalweg, scours, sediment bars and
15 coarse sand deposits (Lastras et al., 2007).

16 During such events, dense cascading shelf waters carry huge amounts of
17 resuspended sediments downcanyon, together with organic matter and
18 pollutants advected from the continental shelf (Guillén et al., 2006; Bourrin et
19 al., 2008; Sanchez-Vidal et al., 2008, 2015; Salvadó et al., 2012, 2017). The
20 finest fraction of such sedimentary flows can stay in suspension for long
21 periods of time (i.e. some years) thereby forming hundreds of meters thick
22 nepheloid layers extending over the slope and deep basin (Puig et al., 2013).
23 This proves that light micro- and macrolitter (e.g. plastics) lying on the
24 continental shelf may easily be swept and transported all the way down the
25 Cap de Creus submarine canyon. Because of their intrinsic properties, plastic

1 items (bags, bottles, cups, fragments) with low drag area behave non-
2 cohesively in marine conditions. Turbulent bottom cascading currents are able
3
4 to provide the shear stress needed to resuspend and transport these objects,
5
6 either as bed load (relatively heavier items), or by saltation or suspension
7
8 (relatively lighter items). Conversely, longlines and ropes, and nets would not
9
10 have been dragged down canyon since they usually are strongly caught
11
12 around outcropping rocks, hard grounds and cold-water coral colonies (see
13
14 Sections 3.2 and 3.4) in the canyon head, thus severely limiting chances for
15
16 transportation. Other ALDFG items, such as bottom trawling nets found on
17
18 soft bottoms, would seem too big and heavy to be transported by those
19
20 currents. However, it has been observed for these currents to cause about
21
22 400 kg mooring anchor weights left on the sand-filled canyon thalweg to move
23
24 down by several kilometers while dragging the entire mooring just in few days
25
26 (Puig et al., 2008), which illustrates the tremendous transport capacity these
27
28 currents have. In fact, the highest number of bottom trawl nets reported in this
29
30 study (Dive 42) appeared in an area of the canyon head that according to
31
32 VMS records (unpublished data) is not frequented by trawlers. This could be
33
34 an indication that bottom trawl nets abandoned on the northern shelf could be
35
36 pushed towards the canyon head, where they could end up entangled around
37
38 rocks. All the above provides a robust explanation of the litter class sorting
39
40 observed in Cap de Creus Canyon, with ALDFG concentrating in the canyon
41
42 head and lighter objects being washed away to the deepest part of the canyon
43
44 floor. Tubau et al. (2015) had formerly suggested the above-described litter
45
46 funneling process towards deeper canyon reaches, which then become litter
47
48 accumulation zones. The results presented here bring in a wealth of data from
49

64
65

1 shallower domains than those considered in Tubau's work, thus allowing an
2 extensive comparison and providing an improved understanding of the
3 magnitude of the cleaning role of the continental shelf by high-energy natural
4 oceanographic processes. Finally, it could be hypothesized that these
5 processes may have an even larger influence on the distribution of
6 microplastics at larger scale, since small plastic particles could be easily
7 washed away through submarine canyons towards deeper areas, generating
8 accumulations areas beyond 2000 m, as already suggested by Sanchez-Vidal
9 et al. (2018). The presence of large deposits of microplastics on the deep sea
10 could have far reaching consequences than previously thought, especially if
11 they become part of the diet of some deep-sea species (Carreras-Colom et
12 al., 2018; Cau et al., 2019), which could introduce this fragmented plastic into
13 the food chain and eventually generate problems of food security.

31 **4.3. Interactions of longlines with cold-water corals**

32 It has been recognized that longline fishing has a far smaller impact on
33 vulnerable marine ecosystems than commercial bottom trawling (Pham et al.,
34 2014a). This does not mean that its effects over the benthic fauna should be
35 overlooked, especially in coral rich areas where an intense activity of bottom
36 longlining exists (Bo et al., 2014; Consoli et al., 2019). We have assessed the
37 impact of abandoned longlines on the three main cold-water coral species
38 occurring in Cap de Creus Canyon as a proxy for the level of impact this
39 fishing practices may have over the benthic community in its entirety.
40 Whereas the number of coral colonies affected differed from one dive to
41 another, the highest percentage of entanglement occurred in areas where the
42 density of longlines was higher. Overall, 10% of all cold-water colonies

65

1 identified in the video footage had lines entangled around them, a situation
2 that could lead to suffocation, branch breakage, abrasion, epibiosis, infection
3 and ultimately the death of colonies (Galgani et al., 2018). Compared to other
4 locations in the Mediterranean Sea, where up to three times more corals have
5 been reported to be affected by longlines (Angiolillo et al., 2015; Bo et al.,
6 2014), the value we have found in Cap de Creus Canyon appears rather low.
7 However, video footage may offer a partial view of the real impact caused by
8 longlines, as it provides limited information on how many colonies are partially
9 broken and no information at all on colonies that have been fully removed
10 from their natural habitat due to such fishing practices. If properly recorded,
11 by-catch data from fishing boat logbooks could bring complementary
12 information to better assess the percentage of coral colonies broken or
13 entirely removed by longlining yearly. It seems also plausible that loose
14 longlines, ropes and net fragments, together with their loose ends and
15 hanging sections, could be swung and moved down by the strong bottom
16 currents measured in the Cap de Creus canyon head and beyond. This might
17 favor secondary entanglement around already entangled colonies and on new
18 colonies, with the associated damage this could cause.

44 **4.4. Management implications**

45 As part of the ecosystem-based approach to management that should be
46 implemented in the SCI “South-West Gulf of Lions canyons system”, local and
47 national authorities may consider using the results of this study when
48 designing mitigation measures to tackle the threat posed by the accumulation
49 of marine litter over the seabed. In this sense, maintaining or improving the
50 quality of the marine ecosystem of Cap de Creus could only be achieved by
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1 means of (1) a drastic reduction of the litter inputs (i.e. strict control of land
2 and sea-based sources) and possibly (2) through specific actions set to
3 remove some of the objects currently found over the seabed. The
4 development of such measures would be in line with initiatives already
5 launched at the European level (e.g. European Commission, 2019), which are
6 now seeking solutions for the removal of existing marine litter (notably plastics
7 and microplastics) to limit the damage over the benthic ecosystem. In the
8 specific case of Cap de Creus, since all litter items identified in the video
9 footage are now accurately georeferenced, it could be possible to attempt the
10 recovery of some of the debris found in certain accumulation areas or litter
11 hotspots, especially in trawlable grounds inside the submarine canyon. In
12 these cases, each attempt should weight the benefits of removing large
13 amounts of marine litter against the potential impact on the benthic fauna
14 produced by trawl net, especially in those areas that are currently free of
15 trawling. The video images used together with the multibeam bathymetry of
16 the submarine canyon could be a powerful tool to assess the feasibility of
17 each action and the consequences of its implementation.

36
37
38
39
40
41 In the same way, abandoned trammel and trawl nets could also be retrieved
42 to reduce future damage. Although these procedures are much simpler in
43 shallow waters, where SCUBA divers can operate generating the minimum
44 damage possible (see a protocol for the extraction of lost nets in Hereu and
45 Ylla, 2017), there exists the possibility of using, for instance, a vessel-towed
46 “creeper” (Graham et al., 2009) to retrieve selected nets from deeper soft-
47 bottom areas. Such an operation, which has proven satisfactory to remove
48 gillnets in deep-sea areas in Norway and Rockall and Porcupine banks (Large
49

62
63
64
65

1 et al., 2009), would be relatively cheap and simple to implement. Joint actions
2 with local fishermen, who have a strong knowledge of the seabed after many
3 years of experience, could facilitate the retrieval of ALDFG, while helping
4 raising awareness of the impacts that their activities may have over the
5 benthic ecosystem and, ultimately, in the catches they are interested in.
6 Initiatives such as Fishing for Litter (www.fishingforlitter.org.uk), Projecte
7 Marviva
8 ([http://residus.gencat.cat/ca/ambits_dactuacio/tipus_de_residu/deixalles-
10 marines/projectes/projecte-marviva/](http://residus.gencat.cat/ca/ambits_dactuacio/tipus_de_residu/deixalles-
9 marines/projectes/projecte-marviva/)) and Projecte Evitem la Pesca Fantasma
11 (<http://www.pescafantasma.cat/>) could serve as useful references for the
12 retrieval of abandoned fishing arts.
13

14 Finally, and following the demands of the MSFD, the data provided in this
15 study should be view as a robust reference point in order to monitor the
16 temporal evolution of the marine area, and also to determine the effectiveness
17 of management and mitigation actions developed by regional and national
18 authorities in the forthcoming years.
19

20 **5. Funding**

21 The European Project HERMES (Goce-CT-2005-511234-I), the Spanish
22 Project DEEP CORAL (CTM2005-07756-C02-02/MAR) and the Acciones
23 Complementarias (CTM2007-28758-E/MAR) supported the 2007 cruise on
24 board R/V Garcia del Cid with the manned submersible JAGO. Fundació “la
25 Caixa” sponsored the PROMARES ROV cruise of the University of Barcelona,
26 for which IEO and CSIC provided the Liropus 2000 ROV and R/V Sarmiento
27 de Gamboa, respectively. The EU project Life+ Indemares

Figure 1. Location of the mid-point of the 68 underwater video transects carried out in Cap de Creus mid and outer shelf and submarine canyon to assess the occurrence, abundance and composition of seafloor litter. Dashed lines correspond to the isobaths defining the limits of the inspected domains: northern shelf and southern shelf (80-150 m), canyon head (250-400 m), upper canyon (400-1000 m) and middle canyon (1000-1600 m). The actual path of the dives is not show on the map, but start-end positions of each dive can be found in Supplementary Table 1. Isobaths in meters.

Figure 2. Examples of litter items found in the underwater video transects carried out in Cap de Creus mid and outer continental shelf and submarine canyon. a) Broken single-use plastic bag attached to a lost trammel net on the southern continental shelf, at 110 m depth. b) Glass bottle found on the canyon head at 200 m depth. c) Piece of clothing, likely a fisherman raincoat, found on the canyon head at 305 m depth. d) Car tire found on the canyon head at 272 m depth. e) Large oil drum under a rock cliff found on the canyon head at 270 m depth. f) Amphorae found on the canyon head at 265 m depth. g-h) Several long lines entangled around boulders and rocky outcrops found on the canyon head at around 250-270 m depth. i) Part of a bottom trawl net colonized by sponges, ophiuroids and holothurians, found on the continental shelf. j) Pulling cables from a bottom trawl net found on the southern continental shelf at 115 m depth. k-l) Trammel nets found on the southern continental shelf at 95 and 110 m depth, one of which was still extended and with two spiny lobsters caught in it. Green dots in the screenshots correspond

to the laser points used to measure distances and sizes. Scale bars equal to 30 cm in length. Image credits: © JAGO-Team GEOMAR Kiel / ICM-CSIC.

Figure 3. Seafloor litter density for each category of urban litter (colored) and abandoned, lost or otherwise discarded fishing gears (ALDFG; grey scale) in the different domains surveyed.

Figure 4. Distribution and density of marine litter in Cap de Creus mid and outer continental shelf and submarine canyon. Litter density classes were generated following a Jenks optimization algorithm (Natural breaks). a) Urban litter items. b) Abandoned, lost or otherwise discarded fishing gears (ALDFG). Each circle corresponds to one dive. Isobaths in meters.

Figure 5. Examples of litter accumulation areas or “litter hotspots” on the submarine canyon of Cap de Creus obtained during the PROMARES cruise. a) A bottom trawl net and several ropes with living animals (*Phycis blennoides*, *Bathynectes maravigna* and *Cerianthus membranaceus*) at 484 m depth, illustrating both ALDFG occurrence and the ambiguous interactions between litter and marine organisms. Modified from Tubau et al. (2015). b) Accumulation of a variety of litter items (i.e. an old broken net, plastic bags, an aluminum can and other unidentified objects), part of which half buried, at 1200 m depth. Scale bars equal 30 cm in length.

Figure 6. Model of the average bottom current speed offshore Cap de Creus for the month of February 2012 (details in Section 2.4 and 3.3), when an

intense event of dense-shelf water cascading was recorded (see Durrieu de Madron et al., 2013 for *in-situ* data collected during this period). Arrows indicate current direction. Isobaths in meters.

Figure 7. Some examples of how the bottom longlines get entangled around the main cold-water coral species that occur in Cap de Creus submarine canyon. a-d) Several colonies of *Madrepora oculata* filmed in vertical walls and outcropping rocks with fishing filaments entangled around them. White arrows indicate some of the points of contact with the corals. e) One of the few colonies of *Lophelia pertusa* observed in the canyon head with a nylon filament completely entangled around it. f) Colony of the yellow coral *Dendrophyllia cornigera* with a fishing line entangled around it. Image credits: © JAGO-Team GEOMAR Kiel / ICM-CSIC.

Table 1. Metadata and number of litter items for each of the 68 underwater video transects examined in this study. Geographical positions correspond to approximately the middle point of each dive. Domains: NS: northern shelf (80-150m); SS: southern shelf (80-150m); CH: canyon head (150-400m); UC: upper canyon (400-1000m); MC: middle canyon (1000-1600m). ALDFG: abandoned, lost or otherwise discarded fishing gear.
